Abstract

Aim: The histomorphological changes in the corpora cavernosa following priapism remains an interesting observation due to its pathological and reproductive implications. We investigated the attenuating effect of testosterone and vitamin C on the corpora cavernosa induced fibrosis in priapism of rats.

Methods: Twenty-five Sprague – Dawley male rats were randomly allocated into 5 groups of rats each Group 1 served as the control. Group 2 had only priapism. Group 3 was induced with priapism and then treated with vitamin C. Group 4 was induced with priapism and then treated with testosterone. Group 5 was induced with priapism but were treated with both vitamin C and testosterone. Priapism was induced for one week followed by 6 hours’ post priapism administration of testosterone and vitamin C.

Results: Results showed fibrotic corpora cavernosa in all groups except the control group. Sperm parameters indicated oligospermia and reduced sperm motility especially in group 2 and 3 when compared with the control group.

Conclusion: The results indicated that testosterone and vitamin C ameliorated priapism-induced ischemia – reperfusion injury at different time intervals in rats.

Key words: Priapism, Corpora cavernosa, Infertility, Testosterone, Vitamin C

INTRODUCTION

Priapism is a urological emergency characterised by an unrelenting and painful erection without sexual stimulation usually lasting for longer than 4h to 6h despite orgasm and basically involving only the corpora cavernosa, (Keoghane et al., 2002, Burnett and Bivalacqua, 2007). It is most often drug induced and the antidepressant drug Traxodone has been frequently implicated (Igne et al., 2012). Other psychoactive substances involved in the aetiology of priapism include marijuana, cocaine, ethanol, the atypical antipsychotics; Risperidone, Olanzapine, Clozapine and Quetiapine. Erection is determined by both neuronal and vascular factors with the latter involving essential components of arterial dilatation, relaxation of cavernosal smooth muscle and reduced venous outflow (Azadzoi et al., 1998). Divergence from the coordination of this mechanism alters the response of the erectile tissue and results in Erectile Dysfunction (Parivar F and Lue T.F, 1997). Ischemia, thrombosis, damaged blood vessels of the penis, impair erectile function or impotence has been associated with priapism. Ischemia-reperfusion injury is a complex phenomenon that causes destruction in both local and remote tissues (Sikka, 2016). Although reperfusion of ischemic tissue is necessary for reparative mechanisms, it has been shown to worsen the injury caused by ischemia via release of reactive oxygen species to the systemic
circulation (Munarriz et al., 2003). Oxidative injury develops when there is excessive production of reactive oxygen species and/or free radicals, which exceeds the natural antioxidant defence mechanisms in the body (Munarriz et al., 2003; Akunna et al., 2013). Oxidative stress produces destructive changes in tissues by causing alterations and irreversible cellular damage, (Kaminski K.A, 2002). Ischemic reperfusion injury post treatment with various antioxidants has been evaluated in many organs, (Uluocak et al., 2010). Concomitant administration of androgens and antioxidants has been a subject of debate as it relates to the management of priapism induced impotence. The controversy over the years has been on the efficacy of testosterone. This study was designed to investigate the role of testosterone and vitamin C administered 6 hours after the induction of priapism on the spermatozoa and histomorphology of the corpora cavernosa.

MATERIALS AND METHODS
ANIMALS
Twenty-five adult male Sprague–Dawley rats weighing between 250 and 300g were housed in solid plastic cages in animal house of Anatomy department of the College of Medicine, University of Lagos and allowed to acclimatize for 2 weeks. The animals were later grouped into five rats per cage and maintained at temperatures between 25 – 28°C. The rats were allowed to eat standard rodent chow and water ad libitum throughout the experimental period.

EXPERIMENTAL PROTOCOL
Induction of Priapism
It is a delicate procedure that demands intensive precautionary measures. The penis of rat is a very tender organ and could be easily injured. When traumatized, either by the use of too tight constriction band or rough handling could strangle the penis and impair micturition process resulting in damming of urine within the urinary bladder, ureter or hydro nephrosis and uraemia. This destabilizes the kidneys and becomes a source of infection and renal failure which could lead to death of the rats, (Sanli et al., 2004). Undoubtedly, the following procedure occurred earlier in this index study and 90% of all the first set of rats died. The subsequent use of 2mm slices of size 16F catheter and minimal trauma to the penis was successful. All operations were performed under sterile conditions. The animals were anesthetized with ketamine injection (50 mg/kg, ip). Priapism was induced with the method described by (Sanli et al., 2004). The tip of a 60-cc syringe was applied to the base of the flaccid penis, so a vacuum erection device was created. Before the application of vacuum to the penis, a constriction band, which was cut from 16 Fr Foley catheter in 2-mm slices, loaded around the tip of the vacuum erection device. Then the tip of the syringe was placed at the base of the penis and withdrawn gently to induce erection in the rat penis. After induction of erection in sufficient grade, the constriction band was then placed at the base of the penis by slipping off the syringe. Testosterone was administered intramuscularly at 2.5mg/kg body weight three times weekly (Huang H. F. S and Nieschlag E, 1984) and oral Vitamin C at 25mg/kg body weight daily (Emdex, 2006) throughout the one week of priapism induction.

Animal groupings
The animals were divided into five groups containing 5 rats each.

Group 1: Served as the control and was treated with 5ml/kg body weight of normal saline

Group 2: In this group, priapism was induced for one week but no drug was administered

Group 3: Priapism was induced and 6 hours later 25 mg/kg of Vitamin C was injected intraperitoneally.

Group 4: Priapism was induced and 6hrs later 2.5mg/kg body weight of testosterone was injected intramuscularly at three times weekly.

Group 5: Priapism was induced and 2.5mg/kg body weight of testosterone and 25mg/kg body weight of vitamin C injected via same route as above. The animals were sacrificed one week after priapism induction. The penis and the seminiferous tubules were harvested for histology and seminal fluid analysis.

Tissue preparation for histological analysis
All rats were penectomized 1 week after the induction of priapism and the penis were fixed in Bouin’s solution for 24 hours and then dehydrated by passing through ascending grades of alcohol (70%, 80%, 90% and absolute alcohol). After dehydration, tissues were cleared in xylene, infiltrated, and then embedded in paraffin wax. Each penis was sectioned along horizontal axis in 5um thickness. Two sections from each rat were blocked in paraffin. Two sections of each block (total 4 sections for each testis) were stained with Haematoxylin and Eosin (H & E) according to routine light microscopic procedures.

Protocol for Haematoxylin and Eosin stain
(Ehrlich’s Haematoxylin)
Tissue sections were taken to water and stained with Mayer’s Haematoxylin for 10 minutes. The
sections were then washed in water, differentiated in 1% acid alcohol for 1 minute and blued in Scot’s tap for 2 minutes. Section was washed in water and stained in aqueous eosin for 20 seconds. Tissues sections were washed in water, dehydrated in 2 changes of alcohol, cleared in 2 changes of xylene and mounted in Diselene Pthalate xylene (DPX) and air dried.

Sperm Count
Following penectomy, the caudal aspect of the epididymis of each rat was excised and dipped into a solution of normal saline to enable the sperm cells to swim out. Haemocytometer chambers (Biocotec 1280 Zhejiang, China mainland) were prepared for counting according to the WHO criteria for semen analysis. Spermatozoa were viewed and counted under a light microscope. The haemocytometer was divided into nine fields. Spermatozoa were counted and recorded for just five random fields and the values recorded in million (10⁶) (Tomlinson et al., 2001).

Sperm Motility
Semen was collected from the caudal epididymis and assessed for motility using rapid forward progression, medium forward progression and slow forward progression. Each sample was accessed twice. For consistency, all readings were carried out at 37°C, (WHO, 2000).

Sperm Morphology
After liquefaction and prior to staining, an aliquot of semen was washed with Quinn’s Sperm Washing Medium, SAGE (USA) and centrifuged at 3000rpm for 10 minutes. The supernatant was removed and 0.5 mL of Quinn’s medium was added to the remaining pellet. 10 µL of washed semen was then spread onto a glass slide, fixed and air-dried. The smears were washed with distilled water and stained with Spermac stain, Ferti Pro (Beernem, Belgium). After staining, the smears were washed with distilled water. Two different examiners counted 200 cells per smear using bright field illumination at final magnification of 100x and oil immersion. Strict criteria (Menkveld, et al., 1990) were applied for the evaluation, according to which a spermatozoon is normal if it has an oval head, 4.0–5.0 µm long and 2.5–3.5 µm wide, measured with an ocular micrometer. The length-to-width ratio should be 1.50–1.75. A normal spermatozoon has a well-defined acrosome that covers 40%–70% of the head. The midpiece is thin, less than 1 µm wide, about 1.5 times longer than the head. Cytoplasmic droplets, if present, should not be larger than half of the head width. The tail is thin, uniform, uncoiled and about 45 µm long. According to this classification system, all borderline forms are considered as abnormal.

Statistics
Statistical analysis was done using SPSS statistical software (version 7). Paired T test was used to compare mean values between the control group and other groups in the study. The comparison was done for sperm count, sperm motility, sperm morphology, liver enzymes and haematological indices.

RESULTS
Histomorphological study
Fig 1 and fig 2 shows result for control group 1 demonstrating normal tissue and cellular microstructure of the penis. Fig 3 and 4 (Group 2) was the Priapism induced group without treatment. show cellular changes and tissue fragmentation in the penile tissues. Fig 5 and 6 (Group 3), demonstrates Spongiform corpora cavernosa with dilated vascular spaces (fig 5) and fibrotic corpora cavernosa tissues (fig 6). Fig 7 and 8 (Group 4) shows preserved tissue and cellular structures with mild fibrotic tissue while fig 9 and fig 10 (Group 5) also shows similar results.

DISCUSSION
The pathophysiology of priapism can be simplistically viewed as dysfunctional hemodynamic process of the penis, whereby the genital organ excessively endures blood engorgement and the major point of this phenomenon is the anoxia of penile tissue (Burnett, 1995). In anoxic state, smooth muscle of corpus cavernosum has minimal basal tension and has no spontaneous contractile activity. From the therapeutic view, this study also focused on the responsiveness of corpora cavernosa to testosterone and vitamin C in priapism.

Histomorphological profiles
Histological sections of the penis of control group revealed two pale corpora cavernosa occupying most of the central portion surrounded closely by dense connective tissue, the tunica albuginea (Figure 1 and 2). Also noted is the corpus spongiosum situated ventromedially and containing the slit – like penile urethra surrounded by connective tissue trabeculae and muscle strands, as well as blood vessels and nerves. Histological assessment of group 2 rats (Figure 3 and 4) showed distortions evidenced by extensive fibrosis with thickening of elastic and collagen fibres. Some of these fibres were already transforming into fibroblast. However, testosterone and vitamin C administered 6 hours after priapism induction in P + vitamin C group, P + Testosterone group and P + vitamin C + Testosterone group showed similar fibrotic changes though at a very minimal extent (Figure 5-10). This revealed that testosterone and vitamin C has some level of protective function on the corpora cavernosa.

Seminal Fluid Analysis
As shown in table 1 semen fluid analysis revealed that testosterone administration had potential for boosting up sperm count and motility. The group that received testosterone (group 4 and 5) had optimal values of sperm count and motility when compared to the control group. The mean values of sperm count for group 1, 2, 3, 4 and 5 were 154 x 10^6 cell/ml, 4.9 x 10^6 cell/ml, 4.5 x 10^6 cell/ml, 146 x 10^6 cell/ml and 111 x 10^6 cell/ml, respectively. The sperm motility also showed increase in the recorded values between group 1, 4 and 5. The mean values of fully active sperm motility for group 1, 2, 3, 4 and 5 were 80%, 5%, 20%, 50% and 60% respectively (Table 2). The mean values of normal and abnormal sperm morphology for group 1, 2, 3, 4, and 5 were 80% and 20%, 60% and 40%, 60% and 40%, 70% and 30%, 60% and 40% respectively (Table 3). This revealed that the Testosterone + priapism group had higher normal sperm morphology when compared with the control group. The above results indicate that testosterone has a positive effect on spermatogenesis hence counter the impotent predisposition of the said groups in priapism.

CONCLUSION
We provided evidences for marked carvernosal fibrosis of the penis, oligospermia and reactionary anaemia as a result of experimentally induced priapsm. This implies that besides erectile dysfunction resulting from carvernosal fibrosis, patient may suffer low sperm counts (oligospermia) and severe haemolytic anaemia. Concomitant administration of testosterone and vitamin C significantly reversed the fibrotic effect of priapism on corpora cavernosa and the changes in all of these parameters after testosterone and vitamin C administration were in agreement with previous studies (Allamaneni, et al., 2005). These results demonstrated the beneficial effects of testosterone and vitamin C in spermatogenesis and ischaemic reperfusion injury, as evidenced by changes in seminal fluid analysis and biochemical parameters. This preliminary study will enlighten the researchers with erectile dysfunction to construct more comprehensive studies on the effects of fibrosis, ischemia and reperfusion in cavernosal tissue. Thus, the usage of antioxidant agents in such conditions and clinical implications of antioxidant administration can be improved in the future.
